Computations within a functor context: Semimonads

Intuitions behind adding more "generator arrows"

Example of nested iterations:

$$\sum_{i=1}^{n} \sum_{j=1}^{n} \sum_{k=1}^{n} f(i, j, k)$$

Using Scala's for/yield syntax ("functor block")

- map replaces the last left arrow, flatMap replaces other left arrows
 - ▶ When the functor is *also* filterable, we can use "if" as well
- Standard library defines flatMap() as replacement of map() o flatten

```
► (1 to n).map(j ⇒ ...).flatten is (1 to n).flatMap(j ⇒ ...)
• Functors having flatMap/flatten are "flattenable" or semimonads
```

- Most of them also have method pure: A ⇒ F[A] and so are monads
 - ★ The method pure is not relevant in the functor block
 - ★ We will not need pure in this part of the tutorial; focus on semimonads

What is flatMap doing with the data in a collection?

Consider this schematic code, using Seq as the container type:

```
val result = for {
                                           val result = {
  i \leftarrow 1 \text{ to m}
                                               (1 \text{ to m}).flatMap { i \Rightarrow}
  j \leftarrow 1 \text{ to n}
                                                 (1 to n).flatMap { j \Rightarrow
  x = f(i, j)
                                                    val x = f(i, j)
  k \leftarrow 1 \text{ to p}
                                                    (1 to p).map { k \Rightarrow
  y = g(i, j, k)
                                                       val y = g(i, j, k)
} yield h(x,y)
                                                       h(x,y) \} \} \}
```

Computations are repeated for all i, for all j, etc., from each collection

- All "generator lines" must use the same container type
 - ► Each generator line finally computes a container of that type
 - ▶ The total number of resulting data items is < m * n * p
 - ▶ All the resulting data items must fit within *the same* container type!
 - ▶ The set of *container capacity counts* must be closed under multiplication
- What container types have this property?
 - ▶ Seq, NonEmptyList can hold any number of elements ≥ min. count
 - ▶ Option, Either, Try, Future can hold 0 or 1 elements ("pass/fail")
 - ▶ "Tree-like" containers, e.g. can hold only 3, 6, 9, 12, ... elements
 - "Non-standard" containers: $F^A \equiv \text{String} \Rightarrow A$; $F^A \equiv (A \Rightarrow \text{Int}) \Rightarrow \text{Int}$

Worked examples I: List-like monads

Seq, NonEmptyList, Iterator, Stream

Typical tasks for "list-like" monads:

- Create a list of all combinations or all permutations of a sequence
- Traverse a "solution tree" with DFS and filter out incorrect solutions
 - ► Can use eager (Seq) or lazy (Iterator, Stream) evaluation strategies
 - Usually, list-like containers have many additional methods
 - ★ append, prepend, concat, fill, fold, scan, etc.

Worked examples: see code

- 4 All permutations of Seq("a", "b", "c")
- 2 All subsets of Set("a", "b", "c")
- All subsequences of length 3 out of a given sequence
- **4** Generalize examples 1-3 to support arbitrary length n instead of 3
- 4 All solutions of the "8 queens" problem
- **6** Generalize example 5 to solve *n*-queens problem
- Transform Boolean formulas between CNF and DNF.

Intuitions for pass/fail monads

Option, Either, Try, Future

- Container F^A can hold n = 1 or n = 0 values of type A
- Such containers will have methods to create "pass" and "fail" values

Schematic example of a functor block program using the Try functor:

```
val result: Try[A] = for { // computations in the Try functor
  x \leftarrow Try(...) // first computation; may fail
  y = f(x) // no possibility of failure in this line
  if p(y) // the entire expression will fail if this is false
  z \leftarrow Try(g(x, y)) // may fail here
  r \leftarrow Try(...) // may fail here as well
} yield r // r is of type A, so result is of type Try[A]
```

- Computations may yield a result (n = 1), or may fail (n = 0)
- The functor block chains several such computations sequentially
 - Computations are sequential even if using the Future functor!
 - ▶ Once any computation fails, the entire functor block fails (0 * n = 0)
 - Only if all computations succeed, the functor block returns one value
 - Filtering can also make the entire functor block fail
- "Flat" functor block replaces a chain of nested if/else or match/case

5 / 10

Worked examples II: Pass/fail monads

Type constructors:

- Option[A] $\equiv 1 + A$
- Either[Z, A] $\equiv Z + A$
- Try[A]

 Either[Throwable, A]

Typical tasks for pass/fail monads:

- Perform a linear sequence of computations that may fail
- Avoid crashing on failure, instead return an error value

Worked examples: see code

- Read values of Java properties, checking that they all exist
- Obtain values from Future computations in sequence
- Make arithmetic safe by returning error messages in Either
- Pass/fail chain: sequencing computations that may throw an exception

Worked examples III: Tree-like monads

Examples of tree-like recursive type constructors:

- $F^A \equiv A + F^A \times F^A$ (binary tree)
- $F^A \equiv A + S^{F^A}$ (S-shaped tree, where S is a functor)
- $F^A \equiv A \times A + F^A \times F^A$ (binary tree with binary leaves)
- $F^A \equiv S^A + S^{F^A}$ (S-shaped tree with S-shaped leaves)

Example of a *non-tree-like* type constructor:

•
$$F^A \equiv A + A \times A + A \times A \times A \times A + ...$$
 (powers of 2, non-recursive)

Typical tasks for tree-like monads:

- Traverse a tree, graft subtrees at leaves
- Substitute subexpressions in a syntax tree

Worked examples: see code

- Implement a tree of String properties with arbitrary branching
- 2 Implement variable substitution for a simple arithmetic language

Worked examples IV: Single-value monads

- Pretend that container holds exactly 1 value, together with a "context"
- Usually, methods exist to insert a value and to work with the "context"

Typical tasks for single-value monads:

- Managing extra information about computations along the way
- Chaining computations with a nonstandard evaluation strategy

Examples: see code

- Writer: Perform computations and log information about each step
 - Writer^A $\equiv A \times W$ where W is a monoid or a semigroup
- 2 Reader: Read-only context, or dependency injection
 - ▶ Reader^A $\equiv E \Rightarrow A$ where E represents the "environment"
- Eval: Perform a sequence of lazy or memoized computations
 - ightharpoonup Eval^A $\equiv A + (1 \Rightarrow A)$
- Ont: A chain of asynchronous operations
 - ▶ Cont^A \equiv (A \Rightarrow R) \Rightarrow R where R is the fixed "result" type
- State: A sequence of steps that update state while returning results
 - ▶ State^A \equiv $S \Rightarrow A \times S$ where S is the fixed "state" value type

Deriving the types of single-value monads

Motivation for the choice of the type constructors Writer^A, Reader^A, State^A, Cont^A

We want previous values to be transformed via flatMap to next values

- Writer: a computation $(A \Rightarrow B)$ and some info (W) about it
 - $x^A \Rightarrow f(x) : B \text{ and } x^A \Rightarrow g(x) : W$; the type is $(A \Rightarrow B) \times (A \Rightarrow W)$
 - ▶ this function should have type $A \Rightarrow \text{Writer}^B$, hence $\text{Writer}^B \equiv B \times W$ * use the "arithmetic" Curry-Howard to transform types: $b^a w^a = (bw)^a$
- Reader: Read-only context, or "environment" of type E
 - $x^A \Rightarrow f(r,x)$: B where r^E is fixed; the type is $A \times E \Rightarrow B$
 - ▶ this function should have type $A \Rightarrow \text{Reader}^B$, hence $\text{Reader}^B \equiv E \Rightarrow B$
 - \star we used the "arithmetic" Curry-Howard to transform $b^{ae}=(b^e)^a$
- Cont: A computation that registers an asynchronous callback
 - $x^A \Rightarrow f(cb): 1$ where $cb: B \Rightarrow 1$ (usually, callbacks return Unit)
 - ▶ the type is $A \Rightarrow (B \Rightarrow 1) \Rightarrow 1$; this function should have type $A \Rightarrow \mathsf{Cont}^B$, hence $\mathsf{Cont}^B \equiv (B \Rightarrow 1) \Rightarrow 1$
 - ▶ generalize to $Cont^A \equiv (A \Rightarrow R) \Rightarrow R$ where R is a fixed "result" type
- ullet State: A computation can update state (S) while producing a result
 - $\blacktriangleright x^A \Rightarrow f(x,s)$ and $s^S \Rightarrow g(x,s)$; the type is $(A \times S \Rightarrow B) \times (A \times S \Rightarrow S)$
 - ▶ this will be $A \Rightarrow \mathsf{State}^B$ if $\mathsf{State}^B \equiv (S \Rightarrow B) \times (S \Rightarrow S) \equiv S \Rightarrow B \times S$
 - * we used the "arithmetic" Curry-Howard: $b^{as}s^{as}=(b^ss^s)^a=((bs)^s)^a$

Exercises I

- For a given Set[Int], compute all subsets (w, x, y, z) of size 4 such that w < x < y < z and w + x = y + z
- ② Given 3 sequences xs, ys, zs of type Seq[Int], compute all (x, y, z)such that $x \in xs$, $y \in ys$, $z \in zs$ and x < y < z and x + y + z < 10
- **1** How many chess queens can avoid each other on an $3 \times 3 \times 3$ cube?
- Write a tiny library for arithmetic using Future's; use it to compute 1+2+...+100 via for/yield and verify the result. E.g. implement:

```
const: Int ⇒ Future[Int]
add(x: Int): Int \Rightarrow Future[Int]
isEqual(x: Int): Int ⇒ Future[Boolean]
```

- Read a file into a string and write it to another file using Java Files and Paths API. Use Try and for/yield to make this safe.
- **6** Given a semigroup W, make a semimonad out of $F^A \equiv E \Rightarrow A \times W$
- Implement a semimonad instance for the (recursive) type constructor $F^A = A + A \times A + F^A + F^A \times F^A$
- Find the largest prime number below 1000 via a simple Sieve of Eratosthenes; use the State[S, Int] monad with S = Array[Boolean]
